Question 1.  [5 marks]

Read over the declaration of class BTNode as well as the header and docstring for function has_twins. Then complete the implementation of has_twins.

```python
class BTNode:
    """A node in a binary tree.""

    def __init__(self: 'BTNode', item: object, 
                  left: 'BTNode' =None, right: 'BTNode' =None) -> None:
        """Initialize this node.""
        self.item, self.left, self.right = item, left, right

    def has_twins(T: BTNode) -> bool:
        """Return True if tree rooted at T has a node with two children whose
        items are equal.
        >>> T = BTNode(1, BTNode(2, BTNode(3), BTNode(3)), BTNode(4, BTNode(5), 
                     BTNode(6)))
        >>> has_twins(T)
        True
        >>> has_twins(T.right)
        False
        """
        if T is None:
            return False
        else:
            return ((T.left and T.right and T.left.item == T.right.item) or 
                     has_twins(T.left) or has_twins(T.right))
```

Marking notes: Please give the following amounts for the following incorrect solutions:

- 4 if they only return True when T has two leaves with the same value.
- 4 if they screw up only the None base case; for example, if they compare T.left.item and T.right.item when T is None, but otherwise their solution is correct.

Otherwise: 1 mark for None base case, 2 marks for checking whether T's children have the same values, 2 marks for recursively checking T.left and T.right for twins.

Question 2.  [5 marks]

Read over the declarations of classes BTNode and LLNode, as well as the header and docstring for function root_to_leaves. Then implement the function root_to_leaves.
class BTNode:
    """A node in a binary tree."""

def __init__(self: 'BTNode', item: object, left: 'BTNode' = None, right: 'BTNode' = None) -> None:
    """Initialize this node.
    """
    self.item, self.left, self.right = item, left, right

class LLNode:
    """A node in a linked list."""

def __init__(self: 'LLNode', item: object, link: 'LLNode' = None) -> None:
    """Initialize this node.
    """
    self.item, self.link = item, link

def __repr__(self: 'LLNode') -> str:
    """Return a string that represents self in constructor (initializer) form.
    >>> b = LLNode(1, LLNode(2, LLNode(3)))
    >>> repr(b)
    'LLNode(1, LLNode(2, LLNode(3)))'
    """
    return ('LLNode({}, {})'.format(repr(self.item), repr(self.link))
        if self.link else 'LLNode({})'.format(repr(self.item)))

def __eq__(self: 'LLNode', other: 'LLNode') -> bool:
    """Return whether LLNode self is equivalent to LLNode other"
    return (isinstance(other, LLNode) and
        self.item == other.item and self.link == other.link)

def root_to_leaves(T: BTNode) -> list:
    """
    Return list of paths from T to each of its leaves, or []
    if T is None. Each path is a linked list formed from LLNodes.
    You should return a single-node linked list when T has no children.
    >>> T = BTNode(1, BTNode(2, None, BTNode(3)), BTNode(4, BTNode(5), BTNode(6)))
    >>> L1 = root_to_leaves(T)
    >>> L2 = [LLNode(1, LLNode(2, LLNode(3))), LLNode(1, LLNode(4, LLNode(5))), LLNode(1, LLNode(4, LLNode(6)))]
    >>> len(L1) == len(L2) and all([p in L2 for p in L1])
    True
if T is None:
    return []
elif T.left is None and T.right is None:
    return [(LLNode(T.item, None))]
else:
    leftchpaths = root_to_leaves(T.left)
    rightchpaths = root_to_leaves(T.right)
    leftpaths = [LLNode(T.item, P) for P in leftchpaths]
    rightpaths = [LLNode(T.item, P) for P in rightchpaths]
    return leftpaths + rightpaths

Marking notes: 1 mark for None base case, 1 mark for leaf base case, 3 marks for computing lists of child paths and combining them into list of paths from this node.

Question 3. [5 MARKS]
Read over the class declaration for BTNode and the header and docstring for function ordered_and_bounded. Then implement ordered_and_bounded.

class BTNode:
    """A node in a binary tree."
"
    def __init__(self: 'BTNode', item: object, 
                left: 'BTNode' = None, right: 'BTNode' = None) -> None:
        """Initialize this node.
        ""
        self.item, self.left, self.right = item, left, right

    def ordered_and_bounded(T: BTNode, lower: int, upper: int) -> list:
        """Return a list of items, in ascending order, from nodes of T, with all items no less than lower and no greater than upper. Return [] if T is None. You are *not* allowed to sort any list, and you should visit as few nodes as possible.

        preconditions:  -- node items in T are comparable,
                        -- T is a binary search tree in ascending order,
                        that is, all items in every left sub-tree are less than the sub-tree's root and all items in every right sub-tree are more than the sub-tree's root

        >>> T = BTNode(4, BTNode(2, BTNode(1), BTNode(3)), BTNode(6, 
                      BTNode(5), BTNode(7)))
        ""

Page 3 of 5
>>> ordered_and_bounded(T, 2, 5)
[2, 3, 4, 5]

if T is None:
    return []
else:
    return ((ordered_and_bounded(T.left, lower, upper)
        if lower <= T.item else []) +
        ([T.item] if lower <= T.item <= upper else []) +
        (ordered_and_bounded(T.right, lower, upper)
        if upper >= T.item else []))

Marking notes: 1 mark for None base case. 1 mark for getting list from left subtree if lower <= T.item. 1 mark for getting list from right subtree if upper >= T.item. 2 marks for adding T.item to list if it is in interval [lower, upper]. 1 mark off if extra nodes are visited, that is BST property not used. 1 mark off if list is sorted.

Question 4.  [6 MARKS]

Read the functions hybrid_search and hybrid_search2. For each function, decide which of the following complexity classes best describe that function’s worst-case performance on a list of n elements:

\[ O(1) \quad O(lg n) \quad O(n) \quad O(n lg n) \quad O(n^2) \]

For each function, explain why your choice of big-Oh complexity makes sense. Also explain what behaviour you expect hybrid_search and hybrid_search2 should exhibit when run on a computer on a list of size 2n versus a list of size n.

def hybrid_search(x:int,L:list) -> bool:
    """precondition: L is sorted
    >>> L = [1,5,9, 9, 9, 12, 12, 15, 19,20,40,41,42,43,50,100,500]
    >>> hybrid_search(21,L)
    False
    >>> hybrid_search(100,L)
    True
    """
    def helper(i,j) -> bool:
        # precondition: 0 <= i <= j < len(L)
        if (j-i) < len(L)/10:
            return any([y == x for y in L[i:j+1]])
        if x < L[(i+j)//2]:
            return helper(i, (i+j)//2-1)
        elif x > L[(i+j)//2]:
            return helper((i+j)//2+1, j)
        else:
return True
return helper(0,len(L)-1)

$O(n)$. The call to the helper methods occur at most 4 times before $j - i < \text{len}(L)/10$, and then we must search a slice of size between $n/10$ and $n/20$. Then each element in a slice with at least $n/20$ elements must be inspected. I expect the running time to roughly double if I increase the size of the list from $n$ to $2n$.

Marking notes: 2 marks for choosing $O(n)$ with a suitable explanation. 1 mark if their expectation of how running time scales with doubling the list size is consistent with (whatever) choice of complexity class they make.

def hybrid_search2(x:int,L:list) -> bool:
    """precondition: L is sorted
    >>> L = [1,5,9, 9, 9, 12, 12, 15, 19,20,40,41,42,43,50,100,500]
    >>> hybrid_search2(21,L)
    False
    >>> hybrid_search2(100,L)
    True
    """
    def helper(i,j) -> bool:
        # precondition: 0 <= i <= j < len(L)
        if (j-i) < 10:
            return any([y == x for y in L[i:j+1]])
        if x < L[(i+j)//2]:
            return helper(i, (i+j)//2-1)
        elif x > L[(i+j)//2]:
            return helper((i+j)//2+1, j)
        else:
            return True
    return helper(0,len(L)-1)

$O(\lg n)$. The helper method is called approximately $\lg n - 3$ times, and then a linear search of no more than 10 items is performed, so the complexity is proportional to $\lg n$. I expect that the running time would increase by a constant as the size of the input list was doubled.

Marking notes: 2 marks for indicating $O(\lg n)$ and giving a suitable explanation. 1 mark for indicating that run time would increase by a constant if the length of the input list were doubled.
